Topics

- Parameter estimation for discrete probability tables.
- Structural learning of discrete Bayesian networks.
- Learning structure from large datasets exploiting pairwise marginals
- Testing (conditional) independence of continuous random variables for learning structure of continuous Bayesian networks.

Pretty much a non-Bayesian talk, more engineering.

Parameter estimation for discrete BNs

Basic to learning the structure of a discrete Bayesian network is some method for estimating marginal or conditional probability tables, for use in (a) score based methods or (b) conditional independence test methods.

- Usual to have a complete dataset
- Here relax to incomplete data, assuming Missing At Random (MAR)

 Specifically advocate use method in AISTATS '99 paper, based on maximum entropy. Estimate joint distribution of two binary variables X and Y from incomplete dataset.

Introduce random variables: $X^* \in (x_0^* \equiv ?, x_1^* \equiv x_1, x_2^* \equiv x_2)$ and $Y^* \in (y_0^* \equiv ?, y_1^* \equiv y_1, y_2^* \equiv y_2)$.

In terms of these variables, the dataset is complete.

	<i>Y</i> =?	$Y = y_1$	$Y = y_2$
<i>X</i> =?	<i>n</i> 00	<i>n</i> ₀₁	<i>n</i> ₀₂
$X = x_1$	<i>n</i> ₁₀	<i>n</i> ₁₁	<i>n</i> ₁₂
$X = x_2$	<i>n</i> ₂₀	<i>n</i> ₂₁	n ₂₂

Set $p_{ij,kl} := P(x_i, y_j, x_k^*, y_l^*)$. Under MAR assumption, we have non-linear constraints:

$$\begin{array}{rcl} p_{ij,00} &=& P(x_i,y_j)P(x_0^*,y_0^*) \\ p_{ij,i0} &=& P(y_j \mid x_i)P(x_i^*,y_0^*) \\ p_{ij,0j} &=& P(x_i \mid y_j)P(x_0^*,y_j^*). \end{array}$$

Maximize entropy the joint distribution $P(X, Y, X^*, Y^*)$, subject to constraints, by iteration. Then marginalize to get the desired estimate of P(X, Y). Equivalent to EM algorithm.

In a BN, I estimate the conditional table of a node given parents using only the data on the family (hence *local EM*): Estimate the joint, marginalize to parents, then condition.

- Use previous iteration scheme with two or more variables if data incomplete.
- ► Fast compared to full EM, and usually quite accurate.
- Estimates can be used as starting point for full EM estimation in BN.

Equivalence of scoring and conditional independence tests (UAI 2001).

In learning BN structure:

- Assume complete data (discrete).
- Assume node ordering.
- No latent variables.

Then: Incremental structure learning based on

conditional independence tests using cross-entropy, and

score based search using maximum likelihood

are equivalent.

Nested models $g \subset g'$ differing in parent set in one node X_i : $pa(X_i : g') \supset pa(X_i : g)$. Log-likelihood difference of models:

$$\log \frac{L(\hat{p}_{g'})}{L(\hat{p}_{g})} = \sum_{x_i, p \neq (x_i; g')} n(x_i, p \neq (X_i : g')) \log \frac{n(x_i, p \neq (x_i : g')) / n(p \neq (x_i : g'))}{n(x_i, p \neq (x_i : g)) / n(p \neq (x_i : g))}$$

Equal to conditional independence (conditional cross-entropy) test-statistic after scaling:

$$\frac{1}{N}\log\frac{L(\hat{p}_{g'})}{L(\hat{p}_{g})} = \sum_{x_i, pa(x_i:g')} \hat{p}(x_i, pa(x_i:g'))\log\frac{\hat{p}(x_i \mid pa(x_i:g'))}{\hat{p}(x_i \mid pa(x_i:g))},$$

▲日▼▲□▼▲□▼▲□▼ □ のので

So I use the conditional independence testing approach.

Learning structure from large datasets

- Main computational bottle-neck is traversing dataset to estimate joint probabilities for CI tests (uses up to 98% of processing time).
- Look at ways to reduce this using **bivariate** probability tables.

Conjecture $\check{I}_{AC} \leq \min(\check{I}_{AB},\check{I}_{BC}).$

IPF estimation

Suppose during incremental BN building X has parent set Y, and we wish to check if $X \perp \!\!\!\perp Z \mid Y$ for singleton Z. Could estimate P(X, Y, Z) from data, but this could have problems:

- Slow to do this many times.
- ► Table counts could get quite sparse, so estimate of P(X, Y, Z) unreliable

Approximate solution: use IPF (iterative proportional fitting) using bivariate tables to estimate P(X, Y, Z).

IPF estimation

Suppose during incremental BN building X has parent set Y, and we wish to check if $X \perp \!\!\!\perp Z \mid Y$ for singleton Z. Could estimate P(X, Y, Z) from data, but this could have problems:

- Slow to do this many times.
- ► Table counts could get quite sparse, so estimate of P(X, Y, Z) unreliable

Approximate solution: use IPF (iterative proportional fitting) using bivariate tables to estimate P(X, Y, Z).

Lemma

If A, B and C are discrete random variables, and $A \perp B \mid C$, then IPF using bivariate marginals gives the correct joint table P(A, B, C) (starting from uniform joint table).

Advantages of IPF estimation

- Bivariate marginals usually estimated and cached during the initial BN model search stage.
- For 'typical' problems, could expect that estimates should be reasonable: in terms of log-linear models, higher-order interactions have smaller influence on joint distribution 'typically' in natural world.
- Avoids bottleneck problem, no need to traverse the dataset again.
- Fast can also combine with local-EM for estimates using incomplete data.

This seems to work moderately well (at least on a few small examples) though I don't have extensive results to back this up.

Learning continuous BN's from data

Interested in not making distributional assumptions: non-parametric test.

Assume X, Y and Z are continuous. Have a complete dataset, size N.

(ロ)、(型)、(E)、(E)、 E、 の(の)

Learning continuous BN's from data

Interested in not making distributional assumptions: non-parametric test.

Assume X, Y and Z are continuous. Have a complete dataset, size N. For test of $X \perp \!\!\!\perp Y$ use

 $P(x_1 < X < x_2 \text{ and } y_1 < Y < y_2) = P(x_1 < X < x_2)P(y_1 < Y < y_2).$

Estimate various probabilities using frequency counts of data. Use Pearson goodness-of-fit statistic to assess independence

Learning continuous BN's from data

Interested in not making distributional assumptions: non-parametric test.

Assume X, Y and Z are continuous. Have a complete dataset, size N. For test of $X \perp \!\!\perp Y$ use

$$P(x_1 < X < x_2 \text{ and } y_1 < Y < y_2) = P(x_1 < X < x_2)P(y_1 < Y < y_2).$$

For test of
$$X \perp \!\!\!\perp Y \mid Z$$
 use

$$P(x_1 < X < x_2, y_1 < Y < y_2, z_1 < Z < z_2)$$

$$\approx \frac{P(x_1 < X < x_2, z_1 < Z < z_2)P(y_1 < Y < y_2, z_1 < Z < z_2)}{P(z_1 < Z < z_2)}$$

Estimate various probabilities using frequency counts of data. Use Pearson goodness-of-fit statistic to assess independence /conditional independence.

For test of $X \perp \!\!\!\perp Y$, standard Pearson goodness-of-fit test would partition (X, Y) region with rectangular grid.

- How many grid lines?
- Where to place the grid-lines?
- ► For smaller dataset, grid may be too coarse to be useful.
 - Even more so when extending to conditional independence test.

Suggested solution: Median partitioning

Consider test of $X \perp \!\!\!\perp Y$. Instead of making a rectangular grid, make a *random* plane partitioning using the following recursive method:

▲ロ ▶ ▲周 ▶ ▲ 国 ▶ ▲ 国 ▶ ● の Q @

1. Randomly choose X or Y.

Suggested solution: Median partitioning

Consider test of $X \perp \!\!\!\perp Y$. Instead of making a rectangular grid, make a *random* plane partitioning using the following recursive method:

- 1. Randomly choose X or Y.
- 2. Partition dataset into two parts, according to median of chosen variable.

Suggested solution: Median partitioning

Consider test of $X \perp \!\!\!\perp Y$. Instead of making a rectangular grid, make a *random* plane partitioning using the following recursive method:

- 1. Randomly choose X or Y.
- 2. Partition dataset into two parts, according to median of chosen variable.
- 3. Repeat Steps 1 and 2 on the data subsets, recursively, until datasets are smaller than some number of observations (25 say).

Illustration

Illustration

For each rectangular region i, can:

- ▶ Find observed counts *o_i*
- Estimate expected counts e_i based on independence assumption.

▲ロ ▶ ▲周 ▶ ▲ 国 ▶ ▲ 国 ▶ ● の Q @

Find correlation c_i between X-Y values.

These can be cumulated over all regions to give:

- Goodness of fit statistic: $\chi^2 = \sum_{i=1}^{l} (o_i e_i)^2 / e_i$.
 - What distribution does it follow? Probably χ² (Wilks' theorem) but what degree of freedom? Fractal dimension?

- Estimate of I_{XY} : $(1/N) \sum_{i=1}^{I} o_i \log(o_i/e_i)$
 - Note: If independence holds, then $\chi^2 \approx 2NI_{XY}$.
- Root-mean-square correlation $\sqrt{\sum_{i=1}^{I} c_i^2 / I}$.
 - Could also look at $\sum_{i=1}^{l} \operatorname{abs}(c_i)/l$

These can be cumulated over all regions to give:

- Goodness of fit statistic: $\chi^2 = \sum_{i=1}^{l} (o_i e_i)^2 / e_i$.
 - What distribution does it follow? Probably χ² (Wilks' theorem) but what degree of freedom? Fractal dimension?
- Estimate of I_{XY} : $(1/N) \sum_{i=1}^{I} o_i \log(o_i/e_i)$
 - Note: If independence holds, then $\chi^2 \approx 2NI_{XY}$.
- Root-mean-square correlation $\sqrt{\sum_{i=1}^{I} c_i^2 / I}$.
 - Could also look at $\sum_{i=1}^{I} \operatorname{abs}(c_i)/I$

By repeating the partitioning process, distributions of these three quantities may be built up.

Postscript

Following the talk, F. Matus gave me a class of Bayesian networks for which an induced Chow-Liu tree is not a subgraph of the skeleton of the Bayesian network, of which this is an example. Let A and B be independent binary random variables with states $\{0,1\}$ and uniform distribution p(0) = p(1) = 0.5 on each variable. Let X and Y also be binary random variables with states $\{0,1\}$. Make A and B parents of X, with conditional probability table given by p(x|a, b) = 1 if $x = a + b \mod 2$, and zero otherwise. Also make A and B parents of Y with the same logical dependence.

Then all variables in the four node network are pairwise independent, and hence have zero cross-entropy, except for the pair (X, Y) which are logically dependent and therefor have non-zero cross entropy: however there is no direct edge between X and Y.
